Abstract. In this paper we tackle the task of correcting grammatical errors, known as Grammatical Error Correction (GEC). Various errors in text such as punctuation, spelling, grammatical, and choice of words errors are detected and corrected. Communication is crucial in everyone's daily lives, and language is key to sharing information in verbal and written communication. Among all languages, English has an important position due to its global use in business, education, and entrainment. Yet, mastering its grammar can be tough for learners. With rapid commercial use of Grammarly, ChatGPT and QuillBot there is a new focus on GEC domain. In our research paper, we apply the seq2seq neural networks-based on attention in Grammar error correction, using a special type of LSTM model with FastText embedding at the vectorization. The attention mechanism which has been so far popular in Language translation, Computer vision and sentiment analysis has now been deployed in English language grammatical error correction. Validation of the implemented model is done on Lang-8 Corpus. Results show that attention-based model optimizes Grammatical error correction with good GLEU score and less loss.

Keywords: *Grammatical Error Correction, Natural Language Processing, Grammar Checking.*

I. INTRODUCTION

Today, lots of people are learning English as a Second Language (ESL). Learning a new language can be hard, so when one writes, they might make grammatical mistakes. In fact, studies have looked at writings from ESL learners, where the learners write, and English language experts or teacher correct them. These studies found that there are many different types of mistakes in what the learners write [1]. While learning and enhancing knowledge of English Language, learning it through regular writing exercises is one of the most common methods which is adopted by the masses, and therefore writing grammatical error free content indicates one's proficiency in English. Grammar errors could be committed by native writer as well as ESL (English as Second Language) as learning a language is a long process and adopting grammatical rule takes time. Apart from punctuation, verb form errors, there could be spelling mistakes as well, as enhancing vocabulary also takes its own course. Taking human help in correction of mistake committed in writing English Language content from an English

teacher or experts is a difficult and cumbersome task. Therefore, utilizing artificial intelligence for supplementary error rectification is getting popular.

The method of GEC has also improved with the development of methods and technologies based on natural language processing (NLP). First among all method to detect and correct grammar error was the rule-based error correction method. In this approach language specialists or grammar authority sets the rules based on which errors are identified and corrected. The outcomes achieved through this rule-based approach are moderately precise. However, enlarging the rule database demands considerable efforts from the experts and presents challenges in addressing all categories of grammatical errors. Another popular approach in GEC was statistical machine translation (SMT). This method does not require expert knowledge like rule-based methods. In place of rule from language expert, it develops and learns a rectification and correction model from collections of texts from learners that have been aligned at the sentence level and corrected for errors. The limitation of SMT based methods is that it is not easy to acquire collection of texts from learners (corpora). The advancement of deep neural networks (DNN) has found application in grammar and error correction field as well. However, most of these deep learning-based methods focus primarily on the internal composition of individual sentences, they neglect the broader contextual framework, in which each sentence is situated in whole text. In reality, sentences within a text are interconnected semantically to completed text rather than its being an isolated entity. Underscoring the importance of considering contextual cues for accurate grammatical error correction, we propose a deep architecture that captures sentence features across a wider span. By employing an encoder-decoder structure with attention mechanisms, our model incorporates contextual information from neighboring sentences during the error correction process, hence enhancing the grammatical correctness of original sentence. The paper can be outlined as follows: We enhance the conventional input encoder structure by incorporating the Luong dot attention mechanisms. Through the attention mechanism, distinct weights are allocated to each segment and processed within the decoder of the structure. As a result, the process of deciphering the source sentence can effectively leverage its context. We refined the traditional word and character-based embedding algorithm by integrating the FastText embedding method. The structure of this paper is outlined as follows: Initial section is literary survey; this section presents a summary of the relevant literature and research on GEC. In Section 3, we discuss the implementation details of the preprocessing and attention-based grammar error correction models we have developed. Finally, Section 4 offers a summary of our research work and explores potential avenues for future research.

II. LITERATURE SURVEY

Initial work in the domain of GEC concentrated on identifiable categories of errors, including articles and prepositions. Researchers tackled this issue through a combination of manually crafted rules and statistical classification methods [2]. The parser implemented the written rules during error correction. Software company Microsoft developed all rule-based error correction open-source tool Language Tool in early days. However, the field of natural language has uncertainty, flexibility, and complexity

beyond the static rule. To achieve more refined and evolving results, it is essential to expand the quantity of implemented rules, which can lead to a higher likelihood of rule clashes. Techniques which are inherently based on classifiers approach specific error types as classification problems[20], training classifiers with contextual relational features. Makarenko et al. [3] applied Long Short Term Memory (LSTM) to train and selection of words as per the located context of sentence, offering clear gain in the learning of features related to context. Deep neural network-based models are also effective for correcting grammar errors. A study conducted by Hu et al. [4] demonstrated this effectiveness. An Encoder-Decoder architecture based on recurrent neural network (RNN) was designed by Xie and colleagues [5] employing a model which works at character level. They equipped an attention mechanism for handling out-of-vocabulary (OOV) words. They incorporated a beam search algorithm into the model and utilized an n-gram language on the encoder side. Lang et al. [6] examined relevant features in grammar error correction using a logistic regression model. They then condensed these features using a clustering algorithm. Through testing focusing on 10 prepositions and 11 types of grammatical errors, they illustrated the success of their approach. Shi Y [7] et al. constructed applied Bi-LSTM and sequence annotation model, which gave a new vision for Language and GEC. Chollampatt et al. [8] applied CNN neural feature within an encoder-decoder framework. They solved grammar errors while taking whole content in system which was based on phrase. Xie et and colleague [9] proposed an alternative approach, in which they applied character-level sequence to sequence neural model. This unique model was successful in removing the OOV mistake, but it cannot take advantage of word-level information for removing grammar errors. Zhou et al. [10] mechanism that has been applied for finding the appropriate items in history to improve suggestions, and they used attention mechanism with encoder-decoder. They employed a classification model approach to design the GEC model. Additionally, they continuously refined the model by considering the grammatical relationships and hierarchical structure between words. Cheng et al. [11] used a character-level model that works like a sequentially placed neural model. While this model solves the issues where predication is done correctly for the words which were not part of training vocabulary, it doesn't make good use of word-level details for Grammar Error Correction (GEC), even when combined with a separate word-based language model. Although it handles unknown words better, it still struggles with understanding the context of words within sentences for grammar correction. Some Grammer correction model from different language such as Indonesian[12]and Chinese[13] [21][22] are also studied and their approach to apply attention based model in followed. GECToR[14] is utilizes transformer based seq2seq architecture in Grammer error correction but it is computationally expensive and need large data set and training time just to solve grammar error. Some advance method such as Grammarly and GPT3 are not limited to grammar correction task but also works on tone ,vocabulary enablement and plagiarism check etc. feature as well. There comparison with our suggested model cannot fit in due to more parameter coming in picture [15]. All the mentioned methods do satisfactory work in grammar error correction, but they lack in applying the context derived from sentence is correction. In our research paper we discuss the architecture and comparison of grammar

correction model having encoder decoder architecture and an attention layer. The attention layer captures the context and the inherent details within the sentences. Figure 1 below depicts typical encoder decoder model without attention mechanism added in it.

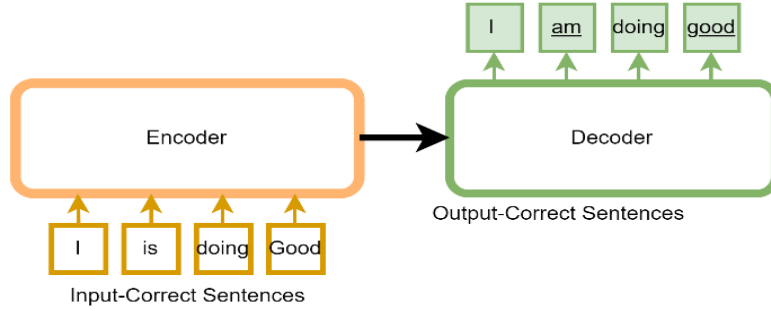

Fig 1: Grammar error correction using Encoder-Decoder models

III. METHDOLOGY AND MODELS

The following steps are employed our preprocessing pipeline.

3.1 Dataset: lang8.train.auto.bea19.m2 data set

Among many available datasets on GEC such as NUCLE[18], ICNALE, CoNLL-2014[19] FCE etc. we have picked Lang-8 Corpus of Learner English dataset from its original source [16]. The sentences in this data set are in a specific format called M2. In this format a text line starting with English alphabet **S** signifies a sentence in its original form, while next line starting with English alphabet **A** represents an annotation done to edit the original sentence. Multiple annotations exist for an incorrect sentence.

Following fig [2] gives an example of M2 format:

```

S This morning I found out that one of my favourite band released his
  new album
A 10 11||R:NOUN:NUM|||bands|||REQUIRED|||-NONE-|||0
A 12 13||R:DET|||a|||REQUIRED|||-NONE-|||0

```

Fig 2: Example from data set in m2 format.

The annotation describes that there is error in noun which is referring to numerical is concept at number 10 position, in the sentence. The other annotation Tell that there is an error in a Determiner, and it should be ‘a new’ album instead of ‘his new’. Therefore,

the correct sentence for above example from data sentence is “This morning I found out that one of my favourite bands released a new album”.

The lang8.train.auto.bea19.m2 is of size 144 MB and this file contains 1037562 sentences ,some of them are grammatically correct sentence not needing any correction ,while some sentences have grammatical errors annotated. This is sufficient data as per dissertation report in GEC field by [17] to compare performance of based model on low scale training and testing computing resources

3.2 Data Cleaning

The original dataset was in specific format called M2 format. Transformation of it was into pairs of accurate and inaccurate sentences, which were saved in a NLP supporting format called comma-separated values (CSV). We removed duplicate and null values from this CSV.

3.3 Data Preprocessing

There were a lot of characters in the dataset which are not part of English punctuation, we removed them, using will use regex. Unlike general NLP tasks data cleaning and preprocessing like stemming, stop word removal, converting each character to lower case, etc. are not relevant here as all these are essential part of English language punctuation.

3.4 Exploratory Data Analysis

We conducted several exploratory data analysis (EDA) tasks to spot any pattern in the dataset. During our analysis of sentence lengths, we observed that the majority of sentences consisted of fewer than 50 words, with very few exceeding this threshold. Through analysis done to measure percentile, we determined that approximately 89% of accurate sentences with no grammar errors had lengths below 22, and 99% were shorter than 38 words. As a result, we excluded sentences longer than 25 words from our dataset to reduce dictionary size and computational costs for grammar correction.

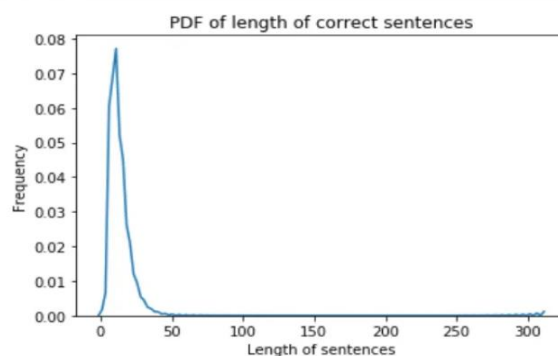

Fig 3: PDF of sentence length

3.5 Encoder-decoder suitable input stream

As we feed word by word data to encoder, not as a whole sentence and then this data is input to decoder, therefore we add special character “#” to denote “start of the sentence” (this will be act as an input to decoder) and add “\$” to denote “end of the sentence” (this will be decoder output).

For example, after doing above operation on data stream sentence “I am doing well.” decoder input will be “# I am doing well.” and decoder output will be “I am doing well. \$”. The full stop punctuation should not be removed or replaced.

Further we tokenized and padded sentences to make their length optimal for training.

3.6 Converting Text to Vector

Tokenized integer in above previous steps are converted to vectors. We have done this step using GloVe, word-to-vec and fast-text embedding techniques. Out of which fast-text embedding was yielding more accuracy in later stage. We have finalized word-to-vec vectorization for this reason.

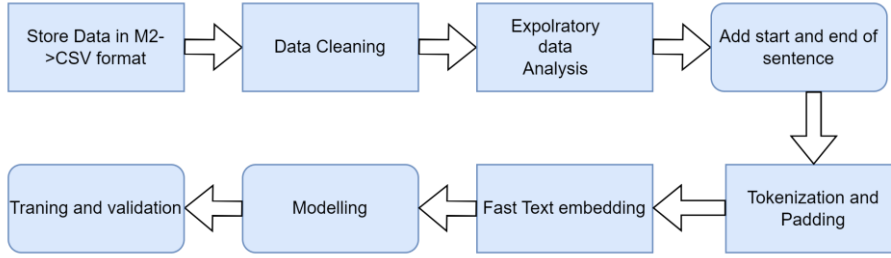

Fig 4: Workflow for Grammar Error correction

3.7 Grammar error correction models

The encoder-decoder model is a type of neural network architecture. It comprises: the encoder and the decoder figure [1]. Building blocks from Encoder decoder are-

Encoder: The encoder takes an input sequence, which is input grammatically correct or incorrect sentences here, and represents it in the form of hidden states and cell states. We have used Kersa library-based LSTM cell at the Encoder end.

Mathematically, the encoder computes the hidden states and cell states as follows:

$$h_t^{\text{enc}}, c_t^{\text{enc}} = \text{EncRNN}(x_t, h_{t-1}^{\text{enc}}, c_{t-1}^{\text{enc}})$$

where x_t : input sample at time stamp t ,

h_t^{enc} : hidden state at time stamp t of the encoder,
 c_t^{enc} : cell state at time stamp t of the input encoder.

Decoder: Based on the representation produced by the input encoder, Decoder at the output end generates the output sequence. During initialization, the encoder representation is passed to the decoder along with a special token indicating the start of the sentence (" <start> "). The decoder then iteratively predicts the next word in the sequence based on the current hidden state and the ground truth tokens.

Mathematically, the decoder computes the hidden states and cell states as follows:

$$h_t^{\text{dec}}, c_t^{\text{dec}} = \text{DecRNN}(y_t, h_{t-1}^{\text{dec}}, c_{t-1}^{\text{dec}})$$

where y_t : input at time step t ,

h_t^{dec} : hidden state at time stamp t of the decoder

c_t^{dec} : cell state at time stamp t of the decoder.

The decoder predicts the next word in the sequence using the hidden state h_t^{dec} and the softmax function:

$$y_t = \text{softmax}(W_{\text{out}} h_t^{\text{dec}} + b_{\text{out}})$$

where y_t : at time stamp t output probability distribution over the entire vocabulary,

W_{out} and b_{out} are the weight matrix and bias vector of the output layer, respectively.

We have implemented multiple grammar error correction models as a base models to compare with attention based model. These models are listed and explained below.

3.7.1 Encoder-Decoder character level model

The encoder takes the input sequence of characters and produces a fixed-length vector representation (embedding) of the entire sequence. The encoder processes each character in the input sequence sequentially and updates its hidden state at each time stamp.

The decoder takes the fixed-length vector representation produced by the encoder and generates the output sequence of characters. Similar to the encoder, the decoder also utilizes RNN cells to process the output end one character at a time. At each time stamp, the decoder predicts the next character in the output sequence based on the current h state and the already generated characters.

The GLEU score for this model was .17 which is low. The representative architecture of this model is illustrated in Figure 4. Here an input word with spelling mistake "PRECISE" is corrected character by character. Each individual character such as P, R, E, C etc. is processed character by character. Whole word PRECISE is not processed.

Fig 5: Encoder-Decoder model with character level model

3.7.2 Encoder-Decoder word level model

Unlike character-level model where individual character are input to encoder, in this model, input and output sequences are represented as sequences of words. This means that each word in the input sequence is individually encoded and processed by the model.

This model improved GLEU score to .74 but MSE loss was high as .21. The representative architecture of this model is illustrated in Figure 5. Here the input sentence stream “I have no money” is corrected word by word. The words such as ,have ,no and money are processed as a word rather than an individual character.

Fig 6: Encoder-Decoder model with word level model

3.7.3 Encoder-Decoder FastText embedding model

This encoder-decoder utilizes FastText embeddings to represent the input sequence. Each word in the input sequence is mapped to its corresponding FastText embedding vector. These embedding vectors capture the semantic and morphological information of the words, allowing the model to better understand the input text as per Bojanowski et al., 2017 [26].

This model exhibits GLEU score to .75 but MSE loss was as .41.

3.7.4 Luong attention model with FastText embedding

We have followed Luong et al [27] model and implemented it for Grammar error correction, it is implemented in figure [4]. We have implemented the dot scoring function of Luong attention model. In the previous models, we were alone using the end hidden state(h) to kick start the output decoder. When sentences are longer in length or have different structure, models without attention layer losses the context. The attention model addresses this challenge by leveraging the hidden(h) states of the encoder at each time stamp when predicting each word.

Fig 7: Encoder-Decoder model with attention layer

IV. CONCLUSION AND FUTURE WORK

This paper implements basic LSTM model with encoder-decoder seq2seq features and adds features of attention layer to them to show improvement in GLEU score and MSE loss as well. The introduction of attention layer enables the decoder to dynamically concentrate on various sections of the input sequence while generating each output sequence word. Rather than depending only on the final hidden state of the encoder, the mechanism of attention takes into account each hidden states of the encoder throughout each time step. This enables the implemented model to weigh the importance of each hidden state based on its relevance to the current decoding step.

Loss values (MSE) and GLEU of each implemented model are presented in following table 1.

MODEL TYPE	LOSS	GLEU SCORE
Encoder-Decoder Character level	.17	.21
Encoder-Decoder word level	.74	.17

Encoder-Decoder word level with FastText	.57	.26
Luong Attention model with FastText	.64	.53

Table 1: Comparison of all the models

In upcoming research, our aim is to expand the Grammar Error Correction (GEC) system by leveraging advanced techniques, with a focus on transitioning from the attention mechanism to transformer-based models. We plan to integrate transformer frameworks, including the Transformer model proposed by Vaswani and colleagues. [23], into our GEC system. These models have demonstrated impressive effectiveness across a range of natural language processing tasks by effectively capturing dependencies over long distances and context dependent correlations. By adopting transformers, we anticipate improvements in the accuracy and efficiency of our GEC system.

We plan to explore techniques for data augmentation and domain adaptation to improve the robustness of the GEC system. This includes generating synthetic training data using techniques such as back-translation and paraphrasing, as well as adapting the model to specific domains or writing styles through domain-specific fine-tuning or transfer learning.

We also plan to add Explanation AI [24] [25] where in this model which would explain every error correction. By integrating this explanatory capability, our system will not only correct errors but also empower users to comprehend the reasons behind the corrections, fostering language learning and improvement.

We are also working in process to implement methods which would tackle noisy corrections and incorrect annotation[27] [28] in lang8 data set .
